Strategies of deception: under-informativity, uninformativity and lies – misleading with different kinds of implicature

Abstract

Conversation is often cast as a cooperative effort, and some aspects of it, such as implicatures, have been claimed to depend on an assumption of cooperation (Grice, 1989). But any systematic class of inference derived from assumptions of cooperation, such as implicatures could also be, on occasion, used to deceive listeners strategically. Here we explore the extent to which speakers might choose different kinds of implicature triggers in an uncooperative game of communication. Concretely, we present a production study in the form of a cooperative or competitive signalling game with the potential of exploiting three kinds of implicatures: exact reading of numeral expressions, scalar implicatures linked to the quantifier some and ad hoc scalar implicatures. We compare how these implicatures are used depending on whether the participants’ co-player is cooperative, a strategic opponent or a non-strategic opponent. We find that when the strategy of the co-player is clear to the participants, the three types of implicatures are used to exploit the co-player’s interpretation strategy. Indeed, participants use numeral implicatures as reliably as truth conditional content in all three conditions, while scalar quantifiers and ad hoc implicature elicit different strategies. We interpret these findings as evidence that speakers expect their interlocutors to infer implicatures from their utterances even in contexts where they know that they will be perceived as uncooperative.

Introduction

Grice (1989) famously presents conversation as a cooperative activity in which participants abide by a cooperative principle, which binds them to make appropriate contributions to the conversation. From this principle follow more specific maxims such as the first maxim of quantity: “Make your contribution as informative as is required” (Grice, 1989, p. 45). Speakers can exploit the maxims in
order to communicate implicit propositions (implicatures) of various types. For example, the speaker can violate the first maxim of quality to communicate a quantity implicature. If I tell you that *I used some of your new shampoo* in a context where it would be relevant and more informative to know whether *I used all of your shampoo*, you may infer that the reason why I am violating the first maxim of quantity is that the more informative statement is not true and therefore infer the implicature that *I did not use all of your shampoo*. The last two decades witnessed a wave of experimental investigation of how different types of quantity implicatures are processed and interpreted; and in harmony with Grice’s account, these investigations have focused on situations where the cooperation and honesty of the speaker is taken for granted. However, conversation also takes place in non-cooperative or competitive situations, where the speaker may be deceptive or uninformative. Politicians are often good examples of unhelpful interlocutors. For instance, consider this evasive answer that Theresa May gave in 2016 when asked whether the UK should have access to the EU single market after Brexit: “What I want to see is the best possible deal for the United Kingdom in trade in goods and services” (Bull, 2016). The use and comprehension of implicatures in non-cooperative settings is a vastly understudied topic. The very few existing comprehension studies on this topic suggest that listeners faced with an uncooperative speaker tend to infer less implicatures than if they are faced with a cooperative speaker (Pryslopska, 2013; Dulcinati & Pouscoulous, 2017; Dulcinati, 2018). Even less work has systematically investigated implicature production in uncooperative contexts. We are aware of only one study which did this (Mol, Verbrugge, and Hendriks, 2005; Verbrugge and Mol, 2008). They had participants play a variant of Mastermind. Players took turns to guess the co-player’s secret sequence of four colours. After each guess, players reported to their co-players the number of matching colours in correct and incorrect positions. In doing so, the reporting player had to choose descriptions from a predefined list. Reporting players had an incentive to be uninformative or misleading, because they would win if their opponent failed to guess their colour sequence correctly after a fixed number of moves. The authors found that some speakers, but not all, tended to select under-informative quantifier expressions.
The study presented in this paper is similar in spirit but goes beyond this work in that it explicitly compares production of different kinds of quantity implicatures and it also provides a baseline cooperative condition for comparison. We believe that it is particularly interesting and timely to fill this gap in the literature, firstly because this method allows us to compare how speakers use explicit and implicit communication strategically, and secondly because it may offer a new perspective on the differences between well studied types of quantity implicatures.

Non-cooperative speakers may differ from cooperative ones in that they may be more likely to deceive or to be uninformative. Although Grice (1989) presents conversation as a cooperative effort, he contemplates both the possibility that speakers may be uninformative by opting out of the cooperative principle or of a maxim in an overt way, for example by saying “I can’t tell you that”, and the possibility that they may be deceitful by covertly violating a maxim. The paramount example of covert violations of maxims is lying, where the liar covertly violates the first maxim of quality (i.e., “Do not say what you believe to be false”; Grice, 1989, p. 46) and intends the audience to remain unaware of the violation. Besides lying, the realm of verbal deception includes falsely implicating. While to lie, at least according to traditional definitions (Isenberg, 1973; Primoratz, 1984), is to say something that the speaker believes to be false with the intention to deceive; to falsely implicate is to communicate something believed to be false by means of a conversational implicature (Meibauer, 2014). For example, if I said that “I used some of your new shampoo” when in fact I believe that I used all of it, I could be falsely implicating that I did not use all of your new shampoo. Although there is an ongoing conceptual debate on whether false implicatures should be considered lies (Meibauer, 2005, 2014) or not (Dynel 2011, 2015) here we will treat them as separate for the purposes of experimental design and analysis. We let the data speak about any potential difference between false implicatures and lies. Therefore the phenomena which we expect to observe with possibly different behavioural signatures in our study are un informativity or Gricean opting out, lies and false implicatures.
Lies are part of what is explicitly communicated, while false implicatures are part of the realm of implicit communication (see Carston, 2002, 2009 and Recanati, 2004 for a review of the implicit/explicit divide). This distinction is likely to impact communication in non-cooperative contexts and whether a speaker goes for telling a lie or, merely, conveying a false implicature. We expect that the use of lies and false implicatures might differ in our study because some aspects of implicit communication make it particularly advantageous in non-cooperative contexts. Indeed, implicit communication offers the advantage of plausible deniability (Pinker, Nowak & Lee, 2010): implicatures are cancellable and therefore speakers can deny having intended to communicate them. I can say *I used some of your shampoo* and later claim I did not mean that I did not finish it. Such denial is, of course, impossible if I explicitly stated I did not use all your shampoo. This feature of implicit communication comes in handy when the speaker wants to communicate something that could incur a penalty, such as proposing a bribe or providing false information. According to Reboul (2017) implicit communication also offers another advantage: hearers might endorse information communicated implicitly more easily than explicit content for two reasons. First, hearers are more vigilant towards content the speaker is strongly committed to, and a higher degree of speaker commitment is carried by explicit, not implicit, content (Morency, Oswald & de Saussure, 2008). Second, hearers are less vigilant towards content that is the fruit of their own inferences, which is the case for implicatures but not for asserted content. All these reasons might push a speaker to prefer false implicatures to explicit lying.

Some previous studies that are similar to the one we are presenting looked at non-verbal deception in the context of signalling games where signallers have to give non-verbal hints (e.g., images, maps) to a receiver player who has to make choices based on the information provided in the hints (Montague et al., 2011; Ransom, Voorspoels, Perfors and Navarro, 2017). Crucially in some cases the game is competitive and the signaler benefits from the receiver’s wrong choices, which provides

---

1 We assume here an explicit/implicit divide corresponding to the distinction between Grice’s *what is said* and what is *implicated*. However, see Carston (2002, 2009) and Recanati (2004) for different perspectives.
motivation to deceive. Signallers can give true hints, false hints, uninformative hints and misleading hints, which like false implicatures consist in conveying a true piece of information which leads the receiver to infer something false. Montague and colleagues (2011) found that their players preferred giving misleading hints rather than false hints. In their game the receiver did not know whether the signaller was cooperative or competitive and they could choose to check whether the hints were false and calibrate their trust accordingly, which was an incentive for the signaller not to be caught lying as it would have reputation consequences for the rest of the game. In a similar competitive game, Ransom, Voorspoels, Perfors and Navarro (2017) gave their participants the options to give to the receiver true, misleading or uninformative visual hints, but not false hints, and they manipulated the signaller’s expectations regarding how suspicious or trustful the receiver would be. Because the receiver did not know whether their signaller was honest or deceitful, the signaller could pretend to be helping the receiver while in fact providing them false or misleading information. They found that when signallers expected a trustful receiver they were more likely to mislead, whereas when they expected a suspicious receiver they were more likely to be uninformative.

These studies are similar to ours firstly because we also employed a competitive signalling game and secondly because the types of deception they studied use the same fundamental mechanisms as the kinds of verbal deception we are interested in, which are to cause someone to have a false belief (Mahon, 2007) either by communicating something false (i.e. false hints, lies) or by communicating something true (i.e. misleading hints, false implicatures).

One important complication of studying explicit and implicit cases of verbal deception is that while the studies on non-verbal deception that we mentioned could draw a clear distinction between false and misleading hints, drawing a distinction between lies and false implicature is not straightforward. In two studies (Coleman & Kay 1981, Hardin, 2010) where participants were asked to rate a false implicature on a scale that ranged from an utterance being a lie to an utterance not being a lie, the average rating was near the middle of the scale. In parallel to these results, studies on the explicit-
implicit distinction in comprehension found that lay-people are likely to consider implicatures part of what is said under some circumstances (Nicolle & Clark, 1999; Doran, Baker, McNabb, Larson & Ward, 2009; Doran, Ward, Larson, McNabb & Baker, 2012). Doran and colleagues (2012) asked participants to judge whether sentences that could give rise to an implicature were true or false in light of a fact contradicting the implicature (e.g., judging whether the sentence I used some of your shampoo is true given that I used all of it). Implicatures arising from cardinal numbers (e.g., I have three cats implicating that I don’t have four) were incorporated into the truth conditional meaning of the utterance 53% of the time, while for scalar implicatures (triggered by quantifiers such and some and most) this happened only in 32% of cases. Weissmann and Terfourafi (2019) used a similar paradigm to investigate whether false implicatures are considered to be lies, looking at several different types of implicatures. They asked participants to evaluate utterances carrying a false implicature on a 7-point scale ranging from “definitely not a lie” to “definitely a lie”. Although most implicatures types were not found to be considered lies, they found like Doran et al. (2012) a difference between numerals and scalar quantifiers: false numerals implicatures were one of the only cases to be clearly considered lies, while their quantifier utterances were rated as neither lies or not lies. These findings all suggest that different types of implicatures differ in how likely they are to be considered part of explicit communication and therefore in whether they are considered to be lies when used deceptively. Different implicature triggers also differ in how easily they give rise to implicatures (van Tiel, van Miltenburg, Zevakhina & Geurts, 2016). This variability is interesting in and of itself. We wanted to explore it, but we also wanted to ensure that our findings would not be restricted to a single implicature type. We therefore chose to use three different types of implicatures in our study.

We focused on three particularly interesting types of quantity implicatures: implicatures arising from numerals, from the quantifier some and from ad hoc constructions, which can all be viewed as types of scalar implicatures (Hirschberg, 1991; Horn, 1972, 1989; van Rooij & Schulz, 2006). For all of them, the implicature arises from the negation of an alternative utterance containing a stronger term on
the same semantic scale. In the case of the quantifier *some* and numerals, these scales are lexicalised and the upper-bound readings in 1a and 2a below, for instance, come from the negation of the stronger alternative in 1b and 2b respectively. Yet, in the case of *ad hoc* scalar implicatures there is no pre-established lexical scale and the scale arises from the context. No lexical scale links Laurel to Hardy, thus in 3a the implicature ‘I didn’t buy a present for Hardy’ could only be derived in a context where the pair is particularly salient and buying them both a present would be relevant.

1a. I used *some* of your shampoo.

1b. I used *all* of your shampoo

2a. I have *three* cats.

2b. I have *four* cats.

3a. I bought a present for *Laurel*.

3b. I bought a present for *Laurel and Hardy*.

There is ongoing theoretical controversy about the nature of inferences associated with different putative implicature triggers. Implicatures linked to *ad hoc* scales are undoubtedly *particularised* implicatures in Gricean (1989) terms since they can only be intended in a context that makes the *ad hoc* scale relevant. By contrast, both scalar terms and numerals have given rise to much theoretical controversy about whether their upper-bound interpretation is the result of an entirely context-dependent implicature or whether it is part of their semantic or *default* meaning (Levinson, 2000; Geurts, 2010). Some theorists argue that lexicalised scalar implicatures linked to quantifiers are an output of grammar (Chierchia, 2004; Chierchia, Fox & Spector, 2012), while others maintain they result from a pragmatic inference. In the latter camp, some defend they are *particularised* implicatures (like *ad hoc* scalar implicatures) and are derived when prompted by context (Geurts, 2010; Noveck & Sperber, 2007), while others maintain they are *generalised* implicatures and that they arise systematically unless the context blocks them (Horn, 1989) or even by default (Levinson,
The interpretation of numerals is also hotly debated with some theorists claiming that they have a lower-bound or at least meaning while the exact interpretation is supplied in context via an implicature (e.g., Horn, 1972; Gazdar 1979; Levinson, 2000) and others claiming that the exact interpretation of numerals is not an implicature but part of their truth-conditional meaning (Carston, 1998; Breheny 2008; Geurts 2006; Kennedy 2015). It is therefore unclear whether we should lump lexical quantifier scales with numerals, with ad hoc scales or whether these are three entirely distinct categories of implicatures.

Empirical evidence has not fully settled the debate about differences between implicature triggers either. It provides some fairly clear evidence setting numerals apart from quantifier scalar implicatures. Papafragou and Musolino (2003) and Huang, Spelke and Snedeker (2013) provide convincing evidence that numerals have an exact truth-conditional interpretation (i.e., three means ‘exactly three’) by showing that pre-school children give exact interpretations of numerals despite finding scalar implicatures notoriously difficult (Noveck, 2001; Papafragou & Musolino, 2003; Pouscoulous, Noveck, Politzer, Bastide, 2007). In the same vein, Huang and Snedeker (2009) found that while adults process the upper bound meaning of scalar terms such as some more slowly than the literal meaning of the quantifier all, they process the exact meaning of numerals just as quickly; suggesting that the former involves drawing a pragmatic inference while the second does not. The comparison between lexical and ad hoc scalar implicatures offers mixed results. Recent experimental evidence suggests that the scalar implicatures linked to quantifiers are derived in the same way as particularised quantity implicatures (see Katsos & Cummins, 2010 for a review). Yet, part of the developmental literature suggests that children have more trouble understanding scalar implicatures with quantifiers than ad hoc implicatures (Barner, Brooks & Bale, 2010; Stiller, Goodman & Frank, 2011), while in contrast Katsos (2009) suggests they calculate both types of implicatures to the same extent. Finally, somewhat in opposition to previous studies, Rees & Bott

---

2 More precisely, Carston (1998) argues that cardinals have an underspecified meaning and that whichever sense they assume in context (i.e., at least, at most or exactly) contributes to the truth conditional meaning of the utterance.
(2018) found lower rate of implicature readings for *ad hoc* expressions than for the quantifier *some* or numerals in a study using a structural priming paradigm. Therefore, despite intensive theoretical and experimental interest in these quantity implicatures for the past decades, the layout of numerals, quantifiers and *ad hoc* scales remains quite blurred with empirical findings that do not always align with each other. It is for this reason that studying the behaviour of these three types of implicatures in non-cooperative contexts is particularly interesting.

Several papers have looked at models of strategic language use in non-cooperative contexts, with special emphasis on the question as to what happens to pragmatic inferences like quantity implicatures when the interests of interlocutors are not fully aligned or even in complete opposition (e.g. Franke, de Jager, and van Rooij, 2012; Asher and Lascarides, 2013; de Jaegher and van Rooij, 2014). An interesting puzzle which arises in this context is that if the non-cooperativeness of a conversational context is commonly known, a rational interpreter would see through any attempt of a speaker to try to mislead with an implicature: rational conversationalists would therefore neither attempt to use, nor be fooled, by a strategically misleading implicature. Franke and van Rooij (2015) discuss how several different assumptions about cognitive limitations of language users can be combined with game-theoretic models of implicature generation in such a way that the above mentioned puzzle dissolves. One suggestion is that language users might only have limited capacity to reason about each other’s perspective.

There is converging evidence for the view that human reasoners can engage in only a fairly limited number of theory of mind reasoning steps in strategic reasoning (e.g. Stahl and Wilson, 1995; Hedden and Zhang, 2002; Keysar, Lin, and Barr, 2003; Crawford and Iriberri, 2007; Camerer, 2003; Meijering et al., 2012). Models of language use that assume possibly limited theory of mind reasoning exist (e.g. Benz and van Rooij, 2007; Pavan, 2013; Rothschild, 2013; Franke and Jäger, 2014) and make predictions about adult performance in situations of strategic language use (e.g. Degen, Franke, and Jäger, 2013; Franke and Degen 2016).
Models of iterated theory of mind reasoning also make predictions about potentially misleading uses of implicature. For example, in the system of strategic reasoning explored by Franke, de Jager, and van Rooij (2012), unstrategic of level-0 theory of mind sophistication do not take their co-player’s perspective into account at all. Since they nonetheless pay attention to semantic meaning, the result is that level-0 speakers produce truthful utterances while level-0 listeners simply interpret all utterances as truthful without considering the speaker’s possible deceptive intent. Level-(n+1) agents, on the other hand, choose an optimal utterance or interpretation based on the belief that their co-player is a level-n agent. So, level-1 speakers assume that their listeners lack strategic capacity to reason about uncooperative language use. These speakers would therefore likely use implicatures to mislead, possibly in the hope that their listeners will not realise their intention to deceive. Conversely, level-2 listener will anticipate an uncooperative speaker’s deceptive intent and believe their utterances to be false, without considering the possibility that the speaker may be double-bluffing. However, if sophisticated speakers and listeners are uncertain about which level of sophistication their co-player is likely to have they might use and expect multi-layered attempts of misdirection. Speakers may then try not to give any information at all, or just use random messages and listeners may also expect this behaviour. But if sophisticated speakers have sufficient evidence to classify their listener as adopting a level-0 or a level-1 strategy they can use this expectation to inform their attempts at misdirecting them.

In the following we therefore explore an experimental paradigm aimed at manipulating participants’ beliefs about the strategic behaviour of the co-player, and observing their choices of expressions to describe an object in cooperative and non-cooperative scenarios with linguistic constructions that include different types of potential implicature triggers.

**Methods**

**Motivation and Design.** In this study we aimed to explore how people use explicit and implicit communication in a non-cooperative context. We asked participants to play a signalling game where
they had to produce verbal hints for a receiver either in a cooperative or in a competitive scenario. Our design is similar to the non-verbal paradigm of Ransom and colleagues (2017), but we relied on linguistic hints which include the possibility of implicatures from different kinds of triggers, and we told participants explicitly that their co-player was aware of the cooperative or non-cooperative situation. This removed the possibility of senders to select messages in such a way as to mask their non-cooperative incentives. Finally, by manipulating participants’ beliefs about the strategic behaviour of their co-player we aimed to reduce the degrees of freedom in the interpretation of the behavioural choices of our participants, thereby allowing us to effectively address the question whether language users are able to mislead with implicatures, triggered by different devices.

We built on previous work by Dulcinati (2018), but add feedback on the co-player’s strategic behavior during an initial training phase, and collect data on each participant’s beliefs about the co-players interpretation of sentences with potential implicature triggers. We adopted Dulcinati’s (2018) card-playing signaling game for two players. Each round of the game involved two cards: a winning green-bordered card and a red-bordered card. The sender knew which was the winning card and had to describe it. The receiver saw the same two cards but did not know which was the winning card. The receiver had to decide which was the correct card with the help of the description made by the sender. Participants in the experiment played the role of the sender; the receiver was a virtual player. Participants were assigned to one of three conditions: a cooperative condition or one of two competitive conditions. In the cooperative condition participants were asked to help the receiver find as many green-bordered cards as possible (a game of pure cooperation, in game theoretic terms), while in the competitive conditions their goal was to make the receiver click on as many red-bordered (losing) cards as possible (a zero sum game). The two competitive conditions different with respect to the co-player’s strategic behaviour during training.

Contrary to Dulcinati (2018) we used a forced-choice design to be able to better gauge the range of answers participants could give: participants were asked to give the receiver a hint using one of
three sentence completion options. Additionally, we aimed to have an engaging realization of the interactive task and told participants, in a form of more extreme deliberate deceit than Dulcinati (2018), that they were currently playing against another real player. By creating a stronger illusion of playing against a human player, we intended to create a more engaging task and to induce more theory of mind reasoning in the participants.  

Finally, we included two additional tasks in order to obtain better control of participants’ likely beliefs about their interlocutor. The experiment included a training phase in which participants obtained information about the choices of the virtual co-player. By exposing different participants to different training regimes, in which the virtual co-player behaved either in a naive or a sophisticated way in the non-cooperative version of the game, we intended to induce a more concrete belief about the co-player’s likely strategic behaviour in the game. We also included a variant of a truth-value judgment task after the main card-playing task, with the help of which we probed participants’ beliefs about their co-player’s interpretation of sentences which have an implicature reading. The data from both of these additional tasks – learning-with-feedback and truth-value judgments – were used to categorise participants into those who (i) learned their co-player’s strategic behavior from training and who (i) responded semantically or pragmatically in the truth-value judgment task. We assumed that only the choices of the participants who successfully learned their co-player’s strategic behavior in the training phase could give clear information regarding their attempts to mislead with an implicature in the main (non-cooperative) card-playing task. For this group of participants, we also assumed that their ability to mislead through implicature would depend on whether they expected their co-player to interpret implicature-triggering sentences in a more semantic or a more pragmatic way.

**Participants.** We collected data from 103 participants (70 female, 33 male; mean age 36.6 years, SD = 12.6 years) via the crowd-sourcing platform Prolific. We recruited participants who satisfied the

---

4 Another difference between our design and that of Dulcinati (2018) was the substitution of the scalar implicature trigger most for the trigger some. Most might allow for unintended additional readings, while some is less ambiguous and better researched regarding its scalar implicature behavior in cooperative contexts.
following pre-conditions, using Prolific’s built-in screening tools: English (any variety) as a first language, minimum of 50% acceptance rate on a minimum of 10 previous experiments on Prolific, and indicated willingness to engage in studies which apply deliberate deceit. Each participant was paid £2.50 for compensation. The experiment description also promised a potential bonus payment of up to £0.75 based on the degree of success in the card-playing game. During the debriefing at the end of the experiment, participants were informed that they had not played against a human co-player. They were also informed that, contrary to what had been advertised in the instructions, they would receive the full bonus payment irrespective of their answers.

**Materials (card-playing task).** The material for a single trial of the card-playing task consisted of a picture depicting two cards – one green-bordered and the other red-bordered – as well as an initial sentence string and three sentence continuations, out of which the participants had to choose one. The initial sentence string was always the same: “The green card is the card where ...”. The three options for completing this sentence differed for the five sentence-type conditions, which were all, none, number, ad hoc and some (see Table 1 for an example of each condition type). The three sentence completion options always corresponded to the categories ‘green’, ‘red’ and ‘opt out’. The ‘green’ sentence continuation would result in a sentence being literally true solely of the green-bordered card in the all and none conditions. In the other (implicature) conditions - number, ad hoc and some- the ‘green’ sentence completion was literally true of both cards, but referred uniquely to the green-bordered card under the sentence’s implicature reading. The same applied, mutatis mutandis, for the ‘red’ option. The ‘opt out’ option resulted in a sentence which was either true of both cards or true of neither card. There were nine different trials for each of the all and none conditions, and six for each of the other three (implicature) conditions - number, ad hoc and some.

**Materials (truth-value judgment task).** The truth-value judgment task presented a sentence on each trial with a set of two-alternative forced choice answers: ‘true’ and ‘false’. Sentence material was inspired, and partly borrowed from Noveck (2001). A total of 60 sentences instantiated three conditions: Bizarre, False and Implicature. Examples and numbers of instances are given in Table 2. Sentences in the Bizarre condition were expected to yield ‘false’ judgments, as they involved a nonsensical element such as a type mismatch. Sentences in the ‘true’ condition were expected to receive ‘true’ judgments based on common world knowledge. Sentences in the Implicature condition would be judged true on a literal reading, but false under an implicature reading.

Procedure. The experiment lasted about 20 minutes on average and consisted of two main parts: the card-playing task and the truth-value judgment task. Each participant was randomly assigned to one of three conditions at the beginning of the experiment: the Cooperative, the Unstrategic or the Strategic condition. These conditions influenced the way in which the card-playing task was set-up, as well as the type of feedback the participant would receive during the initial training.

The experiment began by providing general instructions. Participants were informed that there were two parts to the experiment and that both were equally important. It was stressed that this experiment involved playing with another human player, and that therefore participants should pay particular attention to the instructions. Since some of the tasks required normal colour vision to see the – ‘green’ and ‘red’ – card borders, participants saw three plates from the Ishihara color-blindness test (Ishihara 1917) following the general instructions.

Participants were then made familiar with the card-playing game which constituted part 1 of the experiment. Irrespective of the condition each participant was assigned to, the card-playing task was
introduced as an interactive game with another real player. Participants were told that their role was that of the *describer* and that the other player was to play as the *guesser*. Participants learned that there were always two cards in each trial, one bordered by *green*, the other by *red*, referred to as the ‘green card’ and ‘red card’ respectively. They were told that as a *describer* they could see these colours, but not the *guesser*. The *guesser* would see the same cards without coloured borders and possibly in a different spatial arrangement. The *guesser*’s task was to choose the card with the green border, based on the *describer*’s description of it. As *describers*, participants were to select one out of three continuations to complete sentences starting with “The green card is the card where ...”. To ensure a good understanding of the instructions, participants saw an example screenshot of the task from both the *guesser*’s and the *describer*’s points of view (see Figure 1 for examples of the *describer*’s and *guesser*’s task, as presented during the instructions). Participants assigned to the Cooperative condition were instructed to provide a continuation which would enable the *guesser* to choose the green card. Participants assigned to the other two (non-cooperative) conditions were to make the *guesser* choose the red card. We told participants that they would receive a bonus payment proportional to the number of rounds they played successfully, i.e., where the *guesser* managed to pick out the intended card: green in the Cooperative condition and red in non-cooperative conditions.

Before the main test phase of part 1 there were two practice rounds of four trials each. In the first of these, the participants practiced four trials in the role of the *guesser*, without any feedback. They were then told that they were being partnered with another player. Although no actual matching took place, the experiment simulated this process by making participants wait for nine seconds before a message “Pairing successful!” appeared and participants could proceed.
During the second training round, participants played 18 trials in the describer role, exactly as they would in the subsequent test phase. These training sequences used the *all* and *none* items from the main test phase, presented in randomised order. Unlike what would happen in the test phase, participants received feedback for each round after a brief delay, programmed to simulate the co-player making a choice. The co-player’s simulated behaviour was dependent on the condition (Cooperative, Strategic and Unstrategic), except when participants chose the ‘opt out’ option, in which case the co-player was simulated to select a random card. In the Cooperative and Unstrategic conditions, the simulated co-player always interpreted the sentence literally, i.e., choosing the green card when a ‘green’ continuation had been selected and the red card when a ‘red’ continuation had
been chosen by the participant. By contrast, in the Strategic (non-cooperative) condition, the simulated co-player always chose the reverse, e.g., the red card after a selection of ‘green’. Therefore, the Strategic condition meant to induce the belief in participants that their guesser co-player played like a rational agent who consistently chooses a best response to each description, based on the assumption of a non-strategic describer behaviour (corresponding to a level-1 theory of mind strategy). The Unstrategic co-player behaviour instead tried to induce the belief in participants that their guesser co-player might be oblivious to the non-cooperative nature of the game (corresponding to a level-0 theory of mind strategy, i.e., without factoring in the describer’s possibly divergent interests in the game).

Following the training phase, the main test phase of part 1 presented all of the 36 trials in random order. Participants received no feedback on the choices of the virtual co-player, but experienced short pauses of random duration (X-Y seconds) before getting a response to maintain the illusion that they were playing against a real co-player.

The card-game was followed by a self-assessment in which participants adjusted a slider ranging from 0% to 100% to indicate the percentage they believed to have played successfully during the main test phase.

The second part of the experiment began with general instructions. Participants were informed that we wanted to know what they thought about their co-player’s interpretation of certain sentences. The explicit emphasis on participants’ beliefs about the co-player’s interpretation rather than their own was deliberate, since, strictly speaking, the beliefs about co-player interpretation are those that should matter for strategic choice. Admittedly, it may be natural to assume at least prima facie that one’s interlocutor interprets sentences exactly in the same way as we would ourselves. Even if participants did not believe that their co-player’s interpretation might diverging from their own, their answers to these questions should nonetheless indicate the strategic reasons for their choices in the card-description task.
Participants read 60 sentences presented in random order. They indicated whether they thought their ‘partner’ would consider each sentence true or false by clicking on the ‘true’ or ‘false’ button. A short four second interval was built in before the answer buttons appeared, to allow the participants time to read and process the sentence. Initial piloting of the sentence material revealed that without this initial waiting time, the number of pragmatic responses condition was close to zero, i.e., ‘false’ judgments of sentences of the some, most and number” type in the Implicature. This suggests participants might have rushed through the material too quickly to process potential implicatures.

The experiment ended with a debriefing, in which participants were informed about the deliberate deceit and told that they would receive the full bonus payment of £ 0.75 irrespective of their answers on the trials. Finally, participants could, if they wanted, once more provide information on their native language, gender and education level and leave any comments that they might have about the experiment.

**Results**

The randomized allocation of participants to conditions resulted in 39 participants playing the Cooperative condition, 33 for the Unstrategic and 31 for the Strategic condition. Despite occasional minor mistakes (e.g., mistaking a “7” for a “1”), no participant blatantly failed the color blindness test, and so nobody was excluded based on this.

The co-player behaviour exhibited during the training phase with feedback would allow participants, if they were able to learn the behavior of the co-player, to play a unique optimal winning move. The option ‘green’ was the optimal choice in the Cooperative and Strategic condition. The option ‘red’ was optimal for the Unstrategic condition. We looked at each participant’s proportion of choices of the optimal option (out of 18 trials). The mean proportion for conditions was 0.99 in the Cooperative condition, 0.64 in the Strategic condition and 0.52 in the Unstrategic condition. We considered any participant with a proportion of optimal choices of at least 0.5 as having learned successfully during training. This resulted in all 39 participants of the Cooperative condition being categorized as
successful learners, as well as 19 out of 33 participants in the Unstrategic and 19 out of 31 in the Strategic condition.

All items in the True and Bizarre conditions of the truth-value judgement could clearly be identified as true or false based on common world knowledge. We excluded seven participants from further analysis who did not surpass a threshold of 70% correct answers on these items. We use the answers to the some and most condition to probe into participants’ likely beliefs about their co-player’s disposition to compute scalar implicatures. We classified a participant as a pragmatic type if the proportion of ‘false’ judgements in the some and most condition exceeds 0.5; otherwise the

*Figure 2: Proportion of choice options selected by participants who learned successfully during the training-with-feedback session (panels A and B) or did not (panels C and D), and who were classified as pragmatic type (panels A and C) or as semantic type (panels B and D) based on their behavior in the truth-value judgement task.*
participant is classified as a semantic type. A total of 36 participants was classified as a pragmatic type in this way.

Figure 2 shows the proportions of choice options, split by semantic vs. pragmatic type and successful vs. unsuccessful learning. It is apparent that the aggregate behavior of participants with successful learning (subplots A and B) differs strikingly from those who did not learn to play well against their co-player during training with feedback (subplots C and D). The modal choice for successful learners is the winning move for each respective condition. In contrast, there is no clear modal choice or otherwise visually salient pattern in the aggregate data of unsuccessful learners.

As planned, we focus our attention and analyses on the data from participants with successful training results. Our main research questions concern the circumstances which influence the probability that participants choose the winning move. We therefore ran a logistic regression analysis, predicting the log-odds of winning-move choices against non-winning-move choices with predictors CO-PLAYER-TYPE (levels: “cooperative”, “unstrategic”, and “strategic”), CONSTRUCTION (levels: “all”, “none”, “number”, “ad hoc”, and “some”), and IMPLICATURE-TYPE (levels: “semantic”, “pragmatic”). We used the BRMS package (Buerkner 2016) and statistical programming language R (R Core Team 2017), to fit a hierarchical logistic regression with by-item random intercepts using Bayesian inference of a posteriori credible values of model parameters. We fixed wide, largely uninformative priors for fixed-effects coefficients, using a normal distribution with mean 0 and standard deviation 30. We collected 2000 samples from each of 4 chains after a warm-up of 1000 samples and ensured convergence by inspection of traceplots and R-hat statistics. The regression model used the default dummy coding of factors (with “cooperative”, “all” and “pragmatic” as reference levels), but Bayesian inference allows us to compute approximate posteriors for any relevant comparison of (sets of) design cells from the obtained samples. In the following, we will say that the data, when analyzed through this model, provides evidence in favor of the assumption that a combination of factor levels i has a credibly higher proportion of winning-move choices than a
combination of factor levels \( j \), if the posterior level of credence \( P(\delta_{ij} > 0 \mid D) \), given data \( D \), for the difference \( \delta_{ij} \) between log-odds inferred for the estimated coefficients for \( i \) minus that for \( j \) is estimated to be at least 0.95 (Kruschke 2015). We also report below the 95% credible interval of the posterior distribution of \( P(\delta_{ij} \mid D) \).

We start by investigating the main effects that different factor levels have on the average log-odds of winning-move choices. As for main effects of IMPPLICATURE-TYPE, the probability of winning-move choices is credibly higher for pragmatic types than semantics types (\( P(\delta_{ij} > 0 \mid D) \approx 1, \text{ CI } = [0.6717 ; 2.685] \)). Regarding main effects of CO-PLAYER-TYPE, we find that the cooperative condition had a higher probability of winning-move choices than the strategic co-player condition (\( P(\delta_{ij} > 0 \mid D) \approx 1, \text{ CI } = [2.637 ; 8.635] \)), and that the latter had higher winning-move probability than the unstrategic co-player condition (\( P(\delta_{ij} > 0 \mid D) \approx 0.9772, \text{ CI } = [-0.0302 ; 0.8354] \)). For CONSTRUCTION, we find no credible difference between any of “all”, “none” and “number”, but find that “some” has a lower probability of winning-move choices than “none”, which has the lowest observed mean of winning-move choices among the former three (\( P(\delta_{ij} > 0 \mid D) \approx 0.9995, \text{ CI } = [0.552 ; 6.194] \)). Finally, “some” has a credibly higher rate of winning-move choices than “none” (\( P(\delta_{ij} > 0 \mid D) \approx 0.9992, \text{ CI } = [0.3719 ; 1.667] \)).

We look next at the effect of CONSTRUCTION on the winning-choice rates for pragmatic responders. For the Cooperative condition we find that “all”, “none” and “number” are not credibly different, but that “some” is credibly lower than all of the former (\( P(\delta_{ij} > 0 \mid D) \approx 0.9704, \text{ CI } = [-1.541 ; 30.92] \), when compared against “number”) and that “ad hoc” is in turn credibly lower than “some” (\( P(\delta_{ij} > 0 \mid D) \approx 0.9975, \text{ CI } = [0.4731 ; 5.582] \)). For the Unstrategic co-player condition, we find no credible difference between any construction type at all. For the Strategic co-player condition, only “ad hoc” is credibly smaller than any one of “all”, “number” and “none” (\( P(\delta_{ij} > 0 \mid D) \approx 0.994, \text{ CI } = [0.3007 ; 3.838] \), when compared against “number”).
The effects of CONSTRUCTION for semantic responders are as follows. For the Cooperative condition, all of “all”, “none” and “number” are not credibly different, but “some” has credibly lower winning-choice rates than all of the former \(P(\delta_{ij} > 0 \mid D) \cong 0.9945, \text{CI} = [0.23 ; 3.662]\), when compared against “number”), and “ad hoc” has in turn credibly lower winning-choice rates than “some” \(P(\delta_{ij} > 0 \mid D) \equiv 1, \text{CI} = [0.9035 ; 2.43]\). As for the Unstrategic co-player condition, we find no credible difference between “all”, “none” and “number”, but find that “some” has credibly lower winning-choice rates than all of the three former \(P(\delta_{ij} > 0 \mid D) \cong 0.9991, \text{CI} = [0.3975 ; 2.056]\), when compared against “number”). Unlike in the Cooperative condition, the difference between “some” and “ad hoc” is not credibly different in the Unstrategic co-player condition \(P(\delta_{ij} > 0 \mid D) \cong 0.6984, \text{CI} = [-0.536 ; 0.8637]\). Finally, in the Strategic co-player condition we find the exact same pattern as for the Unstrategic condition. Again, “all”, “none” and “number” are not credibly different, but “some” has credibly lower winning-choice rates \(P(\delta_{ij} > 0 \mid D) \cong 0.9975, \text{CI} = [0.4343 ; 2.404]\), when compared against “number”), while “ad hoc” and “some” are not credibly different.

In sum, we find that “number” consistently patterns with “all” and “none”, while “some” and “ad hoc” are almost always associated with credibly lower winning-choice rates. The only exceptions to this pattern are found for participants classified as pragmatic responders in the non-cooperative conditions: in the Unstrategic condition, we find no difference between any constructions, while in the Strategic condition participants chose the winning-move for “some” to an extent that is not credibly different from that of “all”, “none” and “number”.

Discussion

Our participants played in the sender role of a signalling game in which they were either helping or competing against a virtual co-player in the receiver role. Their task was to complete descriptions that could help their co-player choose the winning card from a pair of cards. Some items pushed signallers to convey this hint via assertion and others via implicature (numerals, some, and ad hoc).
Before playing the game participants played a training phase where they could learn the strategy their co-player was using to interpret their instructions. After the game, participants completed a truth-value judgment task in which they indicated how they thought their co-player in the game would have interpreted a series of statements that can give rise to implicatures.

Unless we explicitly indicate otherwise, we will focus our attention on participants who completed the training phase of the card-game successfully. This criterion can be used as a strong indicator that they were paying attention to the instructions, understood them and followed them. Indeed, these participants’ responses to the main card-game task form a fairly coherent pattern of behaviour. By contrast, the picture emerging from the responses of participants who were unsuccessful during learning is erratic, as one would expect if these participants were unwilling or unable to follow the instructions, or hold a specific hypothesis about the co-player’s behaviour. The participants were further divided into semantic and pragmatic responders depending on how they responded in the truth-value judgment task. From the participants who performed successfully during training, twenty-five participants were classified as pragmatic responders, forty-five as semantic responders. The former class, pragmatic responders with successful training, is the theoretically most interesting group for our purposes, because it is here, if at all, that we would expect to see misleading uses of implicatures. Nonetheless, a visual inspection of the data in Figure 2 (panels A and B) suggests a lot of similarities in how pragmatic and semantic responders performed on the card-game task. The distinction between pragmatic and semantic responders might in fact yield interesting additional insights; we will thus consider all successful training participants in our discussion of the findings.

Both semantic and pragmatic participants overwhelmingly chose the winning description in the Cooperative condition. This was expected for pragmatic responders, given that their aim was to help their co-player identified the bonus card. It may be more surprising for semantic responders who expected their co-players to infer implicatures in the context of the game, despite indicating in the truth-value judgment task they did not expect them to infer implicatures ‘in general’. The truth-
value judgement task and the card-game are very different paradigms and it seems plausible that the truth-value judgment task leads us to underestimate some participants’ abilities to take into account implicatures. Indeed, the rate of implicature understanding is generally fairly low when it is assessed by a truth-value judgment task (e.g., 59% in Noveck, 2001; ≤ 60% in Bott & Noveck, 2004; 55% in Mazzarella, Reinecke, Noveck & Mercier, 2018). Ultimately, the semantic responders performance in the Cooperative condition suggests that we should probably be cautious with the distinction we drew between semantic and pragmatic responders based on the truth-value judgment task. Importantly, all participants who passed the training phase demonstrated a rational behaviour in the Cooperative condition. While Dulcinati (2018) also found that participants used the three types of implicatures in his Cooperative condition in his production study, their pattern of responses was much less clear. This may have been due to participants who did not follow the instructions or had no clear hypothesis about the co-player’s behaviour, or due to the more open-ended nature of his production study. Our paradigm is more constrained and we added a training phase, which allows us to focus on participants who definitely understood the strategic aspects of the game. Their behaviour in the Cooperative condition therefore provides a good baseline to assess their strategies in the two competitive conditions.

Pragmatic as well as semantic responders took into account the competitive nature of the card-game in the Strategic and Unstrategic conditions and exhibited different behaviours than in the Cooperative condition. Figure 2 (panels A and B) suggests that all types of responders with successful training used implicatures to deceive their co-players in the Strategic and Unstrategic conditions. This behaviour is enhanced in pragmatic participants, who find implicatures more accessible and presumably find it easier to recruit them to deceive their co-player. Again this general finding echoes Dulcinati’s (2018) production study, in which participants used the three types of implicatures to deceive their co-player in the competitive version of his signalling card-game.
Our production findings seem in line with the two studies conducted on implicature comprehension in non-cooperative contexts, which employed a game setting as we do in the present study (Pryslopska, 2013; Dulcinati, 2018). In both studies participants interpreted descriptions given by an uncooperative speaker and had to decide which ‘card’ or situation the speaker was describing by choosing an option from a set of alternatives including a pragmatic interpretation and a semantic interpretation of the description. Both studies found that participants were less likely to choose the option that matches the pragmatic interpretation of the description when the speaker was uncooperative, compared to when the speaker was cooperative. One key difference with the present study is that neither of these two comprehension studies allowed participants to clearly infer the speaker’s strategy in the game. This means that their participants may have expected more sophisticated strategy whereby the speaker’s implicatures are sometimes true and sometimes false. Indeed, in Dulcinati’s (2018, comprehension) study participants interpreted both assertions and implicatures as false half of the time and true half of the time. The findings from these two comprehension studies are consistent with our production results. Their ‘hearers’’ behaviour mirrors our ‘speakers’’ and they illustrate how listeners expect an un-cooperative speaker’s behaviour to deviate from the cooperative speaker’s consistently truthful use of implicatures.

Interestingly, in our study participants chose the winning description more often in the Strategic than in the Unstrategic condition. As we had anticipated, participants performed the best in the Cooperative condition. This is the simplest condition since it involves no deceit, no complex perspective-taking or reasoning over their co-player’s strategy: participants described what they knew was the winning card. The difference we observe between the Strategic and the Unstrategic conditions, on the other hand, might seem counterintuitive, since the Unstrategic condition involves simple deceit, while the Strategic condition involves double-bluffing – the co-player sees through the deceit and chooses the opposite card from the one misleadingly described (‘green’ when ‘red’ is hinted to). Yet, the participants’ behaviour makes sense when one considers the actions they have to perform on repeated trials. The theory of mind reasoning involved in the Strategic condition for
the participant to select the winning description is the most complex. They have to: 1) pay attention to the ‘green’ card, 2) intend for their co-player to pick up the ‘red’ card, but 3) considering their co-player’s known strategy (from the training phase), and 4) describe the ‘green’ card after all. While the reasoning is complex, this eventually requires a relatively simple action: describe the ‘green’ card, precisely what they would have done in the Cooperative condition. Once it has been thought through, implementing this strategy over a series of trials is straightforward. The Unstrategic condition, on the other hand, involved a simpler misleading strategy: describe to the ‘red’ loosing card since the co-player is Unstrategic and picks up the card communicated to them (as indicated by the training phase). While this reasoning involves fewer levels of meta-representation than that of the Strategic condition, its implementation is more difficult. Describing the ‘red’ losing card requires ignoring the pull towards the ‘green’ winning card, thereby putting participants inhibitory control to the test in every trial.5

Participants did not use the three types of implicature triggers in an identical fashion. All were used to produce implicatures, but not in an equal measure. The most striking effect is the difference between numerals and the two other types of implicature triggers. A main effect indicates that the choices of winning descriptions for numerals patterns with those of all and none control items overall – there is also no difference between them in the Cooperative condition. Participants, thus, used the exact interpretation of numerals as reliably as truth conditional content. This suggests that, if the exact interpretation of numerals is an inference, in our study it was as available as the semantic meaning of the quantifiers all and none. Indeed, while participants used numeral items in a comparable way to the control items, they did so differently from either other implicature triggers, some or ad hoc. Dulcinati (2018) also found in his production study that participants treated numerals exact reading in the same way as the meaning of literal controls, in contrast to ad hoc and

5 Note that in the Cooperative and Strategic conditions the winning description is that of the ‘green’ card, while in the Unstrategic condition it is the description of the ‘red’ card. It is therefore possible to imagine that in the Strategic condition participants simply revert to the easier Cooperative condition strategy. But, since the Unstrategic participants considered here are those who successfully completed the Unstrategic condition training, we can confidently rule out this simpler explanation.
scalar (most) implicatures. This pattern of results echoes that of Weissman and Terkourafi (2019) who found that false numeral implicatures were considered as lies, unlike other implicature types including those linked to scalar quantifiers. All these findings suggest that the exact interpretation of numerals is part of their truth-conditional meaning (Carston, 1998; Breheny 2008; Geurts 2006; Kennedy 2015) and not an implicature (Horn, 1972; Gazdar, 1979; Levinson, 2000) – a conclusion supported by recent experimental evidence on the processing of some and numerals (Marty, Chemla & Spector, 2013).

Numerals are set aside by the specific behaviour – akin to that of literal meaning – they give rise to. Yet, while the responses elicited by some and ad hoc implicatures appear similar and are clearly distinct from those of all, none and numerals, they are not identical to each other. Our regression analysis suggests a credible difference in the Cooperative condition for both pragmatic and semantic responders, where the scalar trigger some prompted more winning description choices than did the ad hoc implicate. The same difference was found for pragmatic responders in the Strategic condition, but not for pragmatic responders in the Unstrategic condition, or semantic responders in either of the two non-cooperative settings, where some and ad hoc were not credibly different. Participants’ reaction to some was therefore sometimes more similar to literal (and numeral) items than ad hoc triggers were. This line of reasoning suggests that scalar implicatures triggered by some are no more difficult, if not perhaps easier to access than those triggered by ad hoc scales. This can be interpreted in two different ways. It can be viewed as an argument in favour of a divide between two types of implicatures, with ad hoc being particularised implicatures and some quantity implicatures, a type of pragmatic inference closer to the truth-conditional content of the utterance (e.g., a Generalised Quantity Implicature for Horn, 1972 or Levinson, 2000; a ‘primary pragmatic process’ for Recanati, 2003).6 We feel the difference we find between some and ad hoc implicature

6 The more extreme version of this line of thought maintaining that implicatures arising from lexicalised scales are default meanings computed automatically (e.g. Levinson, 2000; Chierchia, 2004) is not supported by the data. If this were the case participants should have treated some in the same way as literal triggers (and numerals).
triggers might be insufficient to justify such a strong theoretical distinction – although it is certainly compatible with it. An additional reason for caution is that Dulcinati’s (2018) findings diverge from ours here on this account: he found that scalar implicature with most elicited the same responses as *ad hoc* implicature triggers. We therefore favour a more general interpretation of our results: quantifier and *ad hoc* triggers exhibit an accessibility variability found elsewhere between implicature triggers (Doran et al., 2012; Weissman & Terkourafi, 2009 – note that this variability does not correspond neatly to a divide between *particularised* and *generalised* implicatures or *primary* and *secondary* processes).

In conclusion, we found that cooperative, but also uncooperative, speakers can produce implicatures at least in the kind of signalling card-game we set up in our study. Furthermore, speakers will adapt their use of (false) implicature to the listeners’ typical response behaviour. They exploit implicatures to deceive, but not as consistently as literal meaning (lies) and not equally across the board of implicature triggers. These findings fit well with those of other studies: in production (Dulcinati, 2018), comprehension (Pryslopska, 2013) or using other paradigms (Weissman & Terkourafi, 2019) where (false) implicatures are used and understood in uncooperative contexts, or treated as lies by listeners, but not to the same extent as literal meaning – a distinction also found in the assessment of speaker commitment (Mazzarella et al., 2018). Additionally, what seems to emerge from our results is a scale across numeral, *some* and *ad hoc* items, where the exact reading of numerals is closest to truth conditional content, *ad hoc* scalar implicature furthest and scalar implicatures of *some* somewhere in the middle. We argue that the qualitative distinction on this scale is that between numerals, on the one hand, and *some* and *ad hoc* scales, on the other. While the difference between *some* and *ad hoc* is due to different availability of the upper bound reading between these two implicatures. Further experimental research on the use of implicatures in non-cooperative situations is needed to better understand which factors influence the speakers’ decision to communicate something implicitly or explicitly, as well as the nature of the implicature themselves and the role of cooperation in their derivation.
